

# Optimal Energy Management Policies for Energy Harvesting Sensor Nodes

Vinod Sharma, *Senior Member IEEE*, Utpal Mukherji, *Senior Member IEEE*, Vinay Joseph, and Shrey Gupta

**Abstract**—We study a sensor node with an energy harvesting source. The generated energy can be stored in a buffer. The sensor node periodically senses a random field and generates a packet. These packets are stored in a queue and transmitted using the energy available at that time. We obtain energy management policies that are throughput optimal, i.e., the data queue stays stable for the largest possible data rate. Next we obtain energy management policies which minimize the mean delay in the queue. We also compare performance of several easily implementable sub-optimal energy management policies. A greedy policy is identified which, in low SNR regime, is throughput optimal and also minimizes mean delay.

**Index Terms**—Optimal energy management policies, energy harvesting, sensor networks.

## I. INTRODUCTION

SENSOR networks consist of a large number of small, inexpensive sensor nodes. These nodes have small batteries with limited power and also have limited computational power and storage space. When the battery of a node is exhausted, it is not replaced and the node dies. When sufficient number of nodes die, the network may not be able to perform its designated task. Thus, the life time of a network is an important characteristic of a sensor network ([1]) and it is tied up with the life time of a node.

Various studies have been conducted to increase the life time of the battery of a node by reducing the energy intensive tasks, e.g., reducing the number of bits to transmit ([2], [3]), by choosing the best modulation strategy ([4]), by using efficient transmission scheduling to take advantage of charge recovery phenomenon ([5]), by exploiting power saving modes (sleep/listen) periodically ([6]), using energy efficient routing ([7], [8]) and MAC ([9]). Studies that estimate the life time of a sensor network include [8]. A general survey on sensor networks is [10] which provides more references on these issues.

In this paper, we focus on increasing the life time of the battery itself by energy harvesting techniques ([11], [12]). Common energy harvesting devices are solar cells, wind

turbines and piezo-electric cells, which extract energy from the environment. Among these, solar energy harvesting through photo-voltaic effect seems to have emerged as a technology of choice for many sensor nodes ([12], [13]). Unlike for a battery operated sensor node, now there is potentially an *infinite* amount of energy available to the node. Hence, energy conservation need not be the dominant theme. Rather, the issues involved in a node with an energy harvesting source can be quite different. The source of energy and the energy harvesting device may be such that the energy cannot be generated at all times (e.g., a solar cell). However, one may want to use the sensor nodes at such times also. Furthermore, the rate of generation of energy can be limited. Thus, one may want to match the energy generation profile of the harvesting source with the energy consumption profile of the sensor node. If the energy can be *stored* in the sensor node, then this matching can be considerably simplified. Also, it should be done in such a way that the node can perform satisfactorily for a long time, i.e., at least energy starvation should not be the reason for the node to die. In [11] such an energy/power management scheme is called *energy neutral operation*. Also, in a sensor network, the routing and relaying of data through the network may need to be suitably modified to match the energy generation profiles of different nodes, which may vary with the nodes.

In this paper, we study a sensor node with an energy harvesting source. The motivating application is estimation of a random field which is one of the canonical applications of sensor networks. After sensing, a node generates a packet. This packet needs to be transmitted to a central node, possibly via other sensor nodes. The node may store the packets till they are transmitted. The energy generated can be stored for later use.

Initially, we assume that most of the energy is consumed in transmission only. We relax this assumption later on. We find conditions for energy neutral operation of the system, while keeping the data queue stable. We obtain policies which can support maximum possible data rate. We also obtain energy management policies which minimize the mean delay of the packets in the queue.

## A. Related Work

In the following, we survey the literature on sensor networks with energy harvesting nodes. Early papers on energy harvesting in sensor networks are [14] and [15]. A prototype with solar energy is described in [16]. [17] discusses the various components, design choices, and tradeoffs in efficient design of such a mote. [11] provides various deterministic theoretical

models for energy generation and energy consumption profiles and provides conditions for energy neutral operation. In [18], sleep-wake cycles for a node are obtained that maximize the probability of detection. In [19], the authors obtain a static energy aware multipath routing algorithm for networks with energy replenishment. A recent survey is [12] which also provides an optimal sleep-wake cycle to provide QoS for a sensor node with a solar cell.

### B. Our Contribution

As far as we know, this is the first contribution which provides throughput and mean delay optimal energy neutral policies for energy harvesting sensor nodes. We extend these results to fading channels as well. Most of our policies are in closed form and are easy to implement online.

### C. Paper Organization

The paper is organized as follows. Section II describes the model and provides the assumptions made for data and energy generation. Section III provides conditions for energy neutral operation. We obtain stable power control policies which are throughput optimal. Section IV obtains the power control policies which minimize the mean delay via Markov decision theory. A greedy policy is shown to be throughput optimal and provides minimum mean delay for linear transmission. Section V considers a sensor node when the energy consumed in sensing and processing is nonnegligible. A sensor node with a fading channel is also considered. Section VI compares different policies via simulations. It also provides a real life example. Section VII concludes the paper. The appendix provides proof of a lemma.

## II. MODEL AND NOTATION

In this section, we present our model for a single energy harvesting sensor node.

We consider a sensor node (Fig. 1) which is sensing a random field and generating packets to be transmitted to a central node via a network of sensor nodes. The system is slotted. During slot  $k$  (defined as time interval  $[k, k + 1]$ , i.e., a slot is a unit of time),  $X_k$  bits are generated by the sensor node. Although the sensor node may generate data as packets, we allow arbitrary fragmentation of packets during transmission. (Zigbee allows byte level fragmentation. We will see in Section IV that arbitrary fragmentation provides

a reasonable approximation.) Thus, packet boundaries are not important and we consider bit strings (or just fluid). The bits  $X_k$  are eligible for transmission in  $(k + 1)$ st slot. The queue length (in bits) at time  $k$  is  $q_k$ . The sensor node is able to transmit  $g(T_k)$  bits in slot  $k$  if it uses energy  $T_k$ <sup>1</sup>. We assume that transmission consumes most of the energy in a sensor node and ignore other causes of energy consumption (this is true for many low quality, low rate sensor nodes ([13])). This assumption is removed in Section V. We denote by  $E_k$  the energy available in the node at time  $k$ . The sensor node is able to replenish energy by  $Y_k$  in slot  $k$ .

We initially assume that  $\{X_k\}$  and  $\{Y_k\}$  are *i.i.d.* but will generalize this assumption later. It is important to generalize this assumption to capture realistic traffic streams and energy generation profiles.

The processes  $\{q_k\}$  and  $\{E_k\}$  satisfy

$$q_{k+1} = (q_k - g(T_k))^+ + X_k, \quad (1)$$

$$E_{k+1} = (E_k - T_k) + Y_k \quad (2)$$

where  $T_k \leq E_k$ . This assumes that the data buffer and the energy storage buffer are infinite. If in practice these buffers are large enough (compared to packet size and energy consumed in a slot), this is a good approximation. For example, in an AA-sized NiMH battery, which has a capacity of 7.7 kJ, there is enough energy storage to last a whole night ([11]) and a commercially available low power wireless sensor module TELOS-B has 1 MB external flash for data logging which is enough to store about  $2 \times 10^4$  packets of size 50 bytes. Even if there is not enough storage, these results provide important insights and the policies obtained often provide good performance for the finite buffer case (see Section VI).

The function  $g$  is assumed to be monotonically non-decreasing. An important such function is given by Shannon's capacity formula  $g(T_k) = \frac{1}{2} \log(1 + \beta T_k)$  bits per channel use for Gaussian channels where  $\beta$  is a constant such that  $\beta T_k$  is the SNR. This is a non-decreasing concave function. At low values of  $T_k$ ,  $g(T_k) \sim \beta_1 T_k$ , i.e.,  $g$  becomes a linear function. Since sensor nodes are energy constrained, this is a practically important case. Also, often for the commercially available transceivers (e.g., CC1000, ADF7020, ATA542X Series),  $g$  may be linear for a significant range of SNR. Thus in the following we limit our attention to linear and concave nondecreasing functions  $g$ . This is also a commonly made assumption ([5]). We also assume that  $g(0) = 0$  which always holds in practice.

For practical implementation of (1) and (2), adaptive transmit power, modulation (and/or coding) may be needed. Currently, some commercially available low power transceivers (e.g., CC1000, ADF7020, ATA542X Series) allow this.

Many of our results (especially the stability results) will be valid when  $\{X_k\}$  and  $\{Y_k\}$  are stationary, ergodic. These assumptions are general enough to cover most of the stochastic models developed for traffic (e.g., Markov modulated) and energy harvesting.

<sup>1</sup> A practical sensor node senses and generates a few bytes of data at a time and stores it. The processor can collect from the store a certain number of bytes (depending on the rate allowed in that slot), convert them into a packet and transmits.

Of course, in practice, statistics of the traffic and energy harvesting models are time varying (e.g., solar cell energy harvesting depends on the time of day). But often they can be approximated by piecewise stationary processes. These periods can be long enough for the system to attain (approximate) stationarity and for our results to remain meaningful. Another way to handle this is to assume that  $\{Y_k\}$  is periodic, stationary and ergodic or a regenerative stream which allows modeling solar cell harvesting for many days. Our stability results (and throughput optimal policy) continue to be valid. But, now under these conditions, we obtain periodic stationarity of the  $\{E_k\}$  process; although  $\{q_k\}$  will have stationary distribution if  $\{X_k\}$  continues to be stationary.

In Section III we study the stability of this queue and identify easily implementable energy management policies which provide good performance.

### III. STABILITY

We obtain a necessary condition for stability. Then we present a transmission policy which achieves the necessary condition, i.e., the policy is throughput optimal. The mean delay for this policy is not minimal. Thus, we obtain other policies which provide lower mean delay. In the next section we consider optimal policies.

Let us assume that we have obtained an (asymptotically) stationary and ergodic transmission policy  $\{T_k\}$  which makes  $\{q_k\}$  (asymptotically) stationary with the limiting distribution independent of  $q_0$ . Taking  $\{T_k\}$  asymptotically stationary seems to be a natural requirement to obtain (asymptotic) stationarity of  $\{q_k\}$ . The following Lemma gives a necessary condition for stability of such a policy.

**Lemma 1:** Let  $g$  be concave nondecreasing and  $\{X_k, Y_k\}$  be stationary, ergodic sequences. For  $\{T_k\}$  to be an asymptotically stationary, ergodic energy management policy that makes  $\{q_k\}$  asymptotically stationary (jointly with  $\{T_k, X_k, Y_k\}$ ) with a proper stationary distribution  $\pi$  it is necessary that  $E[X_k] < E_\pi[g(T)] \leq g(E[Y])$ .

*Proof:* Let the system start with  $q_0 = E_0 = 0$ . Then for each  $n$ ,  $n^{-1} \sum_{k=1}^n T_k \leq n^{-1} \sum_{k=1}^n Y_k + \frac{Y_0}{n}$ . Thus, if  $n^{-1} \sum_{k=1}^n T_k \rightarrow E[T]$  almost surely (a.s.), then  $E[T] \leq E[Y]$ . Also then  $n^{-1} \sum_{k=1}^n g(T_k) \rightarrow E[g(T)]$  a.s.

Thus from results on G/G/1 queues [20],  $E[g(T)] > E[X]$  is needed for the (asymptotic) stationarity of  $\{q_k\}$ . If  $g$  is linear then the above inequalities imply that for stationarity of  $\{q_k\}$  we need

$$E[X] < E[g(T)] = g(E[T]) \leq g(E[Y]) = E[g(Y)]. \quad (3)$$

If  $g$  is concave, then we need  $E[X] < E[g(T)] \leq g(E[T]) \leq g(E[Y])$ . Thus  $E[X] < g(E[Y])$  is a necessary condition to get an (asymptotically) stationary sequence  $\{g(T_k)\}$  which provides an asymptotically stationary  $\{q_k\}$ . ■

Now, we present a policy that satisfies the above necessary condition. Let

$$T_k = \min(E_k, E[Y] - \epsilon) \quad (4)$$

where  $\epsilon$  is a small positive constant with  $E[X] < g(E[Y] - \epsilon)$ . We show in Theorem 1 below that it is a throughput optimal policy, i.e., using this  $T_k$  with  $g$  satisfying the assumptions

in Lemma 1,  $\{q_k\}$  is asymptotically stationary and ergodic. In other words, this policy keeps the queue stable if it is possible to do it by any stationary, ergodic transmission policy. Furthermore, under this policy after some time  $E_k > E[Y] - \epsilon$  will always hold and then  $T_k = E[Y] - \epsilon$ . Therefore the service rate will become  $g(E[Y] - \epsilon)$ . Thus the queue is stable if  $E[X] < g(E[Y] - \epsilon)$ . Also the system operates in energy neutral operation. Furthermore, using  $T_k = E[Y] - \epsilon$  means that one does not need to know  $E_k$  exactly which may be difficult to measure in practice. It also does not need  $q_k$ .

**Theorem 1:** If  $\{X_k\}, \{Y_k\}$  are stationary, ergodic,  $g$  is continuous, nondecreasing, concave then if  $E[X_k] < g(E[Y])$ , (4) makes the queue stable (with  $\epsilon > 0$  such that  $E[X] < g(E[Y] - \epsilon)$ ), i.e., it has a unique, stationary, ergodic distribution and starting from any initial distribution,  $q_k$  converges in total variation to the stationary distribution.

*Proof:* If we take  $T_k = \min(E_k, E[Y] - \epsilon)$  for any arbitrarily small  $\epsilon > 0$ , then from (2),  $E_k \nearrow \infty$  a.s. and  $T_k \nearrow E[Y] - \epsilon$  a.s. If  $g$  is continuous in a neighbourhood of  $E[Y]$  then by monotonicity of  $g$  we also get  $g(T_k) \nearrow g(E[Y] - \epsilon)$  a.s. Thus,  $\{g(T_k)\}$  is asymptotically stationary and ergodic and  $E[g(T_k)] \nearrow g(E[Y] - \epsilon)$ . We also get  $E[T_k] \nearrow E[Y] - \epsilon$ . Therefore, from G/G/1 queue results [20] for  $T_k = \min(E_k, E[Y] - \epsilon)$ ,  $E[X] < g(E[Y] - \epsilon)$  is a sufficient condition for  $\{q_k\}$  to be asymptotically stationary and ergodic whenever  $\{X_k\}$  is stationary and ergodic. The other conclusions also follow. Furthermore, since  $g$  is nondecreasing and  $g(0) = 0$ ,  $E[X_k] < g(E[Y])$  implies that there is an  $\epsilon > 0$  such that  $E[X] < g(E[Y] - \epsilon)$ . ■

Thus, (4) is throughput optimal and we denote it by TO.

From results on GI/GI/1 queues ([21]), if  $\{X_k\}$  are i.i.d.,  $E[X] < g(E[Y])$ ,  $T_k = \min(E_k, E[Y] - \epsilon)$  and  $E[X^\alpha] < \infty$  for some  $\alpha > 1$  then the stationary solution  $\{q_k\}$  of (1) satisfies  $E[q^{\alpha-1}] < \infty$ .

Let us consider a policy that does not store the harvested energy. Then,  $T_k = Y_k$  for all  $k$  is a throughput optimal policy under this constraint. It provides stability of the queue if  $E[X] < E[g(Y)]$ . If  $g$  is linear then this coincides with the necessary condition in Lemma 1. If  $g$  is strictly concave then  $E[g(Y)] < g(E[Y])$  unless  $Y \equiv E[Y]$ . Thus this policy provides a strictly smaller stability region. We will be forced to use this policy if there is no buffer to store the energy harvested. This shows that storing energy allows us to have a larger stability region. We will see in Section VI that storing energy can also provide lower mean delays.

Although TO is a throughput optimal policy, if  $q_k$  is small, we may be wasting some energy. Thus, it appears that this policy does not minimize mean delay. It is useful to look for policies which minimize mean delay. Based on our experience in [22], the Greedy policy

$$T_k = \min(E_k, f(q_k)) \quad (5)$$

where  $f = g^{-1}$ , looks promising. In Theorem 2, we will show that the stability condition for this policy is  $E[X] < E[g(Y)]$  which is throughput optimal for linear  $g$  but suboptimal for a strictly concave  $g$ . We will also show in Section IV that when  $g$  is linear, (5) is not only throughput optimal, it also minimizes long term mean delay.

For concave  $g$ , we will show via simulations that (5)

provides less mean delay than TO at low load. However since its stability region is smaller than that of the TO policy, at  $E[X]$  close to  $E[g(Y)]$ , the Greedy performance rapidly deteriorates. Thus it is worthwhile to look for some other good policy. Notice that the TO policy wastes energy if  $q_k < g(E[Y] - \epsilon)$ . Thus we can improve upon it by saving the energy  $(E[Y] - \epsilon - g^{-1}(q_k))$  and using it when the  $q_k$  is greater than  $g(E[Y] - \epsilon)$ . However for  $g$  a log function, using a large amount of energy  $t$  is also wasteful even when  $q_k > g(t)$ . Taking into account these facts we improve over the TO policy as

$$T_k = \min(g^{-1}(q_k), E_k, 0.99(E[Y] + 0.001(E_k - cq_k)^+)) \quad (6)$$

where  $c$  is a positive constant. The improvement over the TO also comes from the fact that if  $E_k$  is large, we allow  $T_k > E[Y]$  but only if  $q_k$  is not very large. The constants 0.99 and 0.001 were chosen by trial and error from simulations after experimenting with different scenarios for different distributions of  $X$  and  $Y$  at different loads. We will see in Section VI via simulations that the policy, to be denoted by MTO can indeed provide lower mean delays than TO at loads above  $E[g(Y)]$ .

Now we show that under the greedy policy (5) the queueing process is stable when  $E[X] < E[g(Y)]$ . In next few results we assume that the energy buffer is finite, although large. For this case Lemma 1 and Theorem 1 also hold under the same assumptions with slight modifications in their proofs.

**Theorem 2:** If the energy buffer is finite, i.e.,  $E_k \leq \bar{e} < \infty$  (but  $\bar{e}$  is large enough) and  $E[X] < E[g(Y)]$  then under the greedy policy (5),  $(q_k, E_k)$  has an Ergodic set.

*Proof:* To prove that  $(q_k, E_k)$  has an ergodic set [23], we use the Lyapunov function  $h(q, e) = q$  and show that this has a negative drift in set  $A \triangleq \{(q, e) : q + e > \beta\}$  where  $\beta > 0$  is appropriately chosen. If we take  $\beta$  large enough, because  $e \leq \bar{e}$ ,  $(q, e) \in A$  will ensure that  $q$  is appropriately large. We will specify our requirements on this later.

For  $(q, e) \in A$ ,  $M > 0$  fixed, since we are using greedy policy

$$\begin{aligned} E[h(q_{k+M}, E_{k+M}) - h(q_k, E_k) | (q_k, E_k) = (q, e)] \\ = E[(q - g(T_k) + X_k - g(T_{k+1})) \\ + X_{k+1} - \dots - g(T_{k+M-1}) \\ + X_{k+M-1} - q | (q_k, E_k) = (q, e)]. \end{aligned} \quad (7)$$

Because  $T_n \leq E_n \leq \bar{e}$ , we can take  $\beta$  large enough such that the right hand side (RHS) of (7) equals

$$E[q + \sum_{n=k}^{k+M-1} X_n - \sum_{n=k+1}^{k+M-1} g(T_n) - g(e) - q | (q_k, E_k) = (q, e)].$$

Thus to have (7) less than  $-\epsilon_2$  for some  $\epsilon_2 > 0$ , it is sufficient that  $ME[X] < E\left[\sum_{n=k+1}^{k+M-1} g(T_n)\right] + g(e)$ . This can be ensured for any  $e$  because we can always take  $T_n \geq \min(\bar{e}, Y_{n-1})$  with probability  $> 1 - \delta$  (for any given  $\delta > 0$ ) for  $n = k+1, \dots, k+M-1$  if in addition we also have  $ME[X] < (M-1)E[g(Y)]$  and  $\bar{e}$  is large enough. This can be ensured for a large enough  $M$  because  $E[X] < E[g(Y)]$ . ■

The above result ensures that the Markov chain  $\{(q_k, E_k)\}$  is ergodic and hence has a unique stationary distribution if  $\{(q_k, E_k)\}$  is irreducible. A sufficient condition for this is  $0 < P[X_k = 0] < 1$  and  $0 < P[Y_k = 0] < 1$  because then the state  $(0, 0)$  can be reached from any state with a positive probability. In general,  $\{(q_k, E_k)\}$  can have multiple ergodic sets. Then, depending on the initial state,  $\{(q_k, E_k)\}$  converges to one of the ergodic sets and the limiting distribution depends on the initial conditions.

#### IV. DELAY OPTIMAL POLICIES

In this section, we consider delay optimal policies. We choose  $T_k$  at time  $k$  as a function of  $q_k$  and  $E_k$  such that  $E\left[\sum_{k=0}^{\infty} \alpha^k q_k\right]$  is minimized where  $0 < \alpha < 1$  is a suitable constant. This minimizing policy is called  $\alpha$ -discount optimal. When  $\alpha = 1$ , we minimize  $\lim_{n \rightarrow \infty} \sup \frac{1}{n} E\left[\sum_{k=0}^{n-1} q_k\right]$ . This optimizing policy is called average cost optimal. By Little's law [21] an average cost optimal policy also minimizes mean delay. If for a given  $(q_k, e_k)$ , the optimal policy  $T_k$  does not depend on the past values, and is time invariant, it is called a stationary Markov policy.

If  $\{X_k\}$  and  $\{Y_k\}$  are Markov chains then these optimization problems are Markov Decision Problems (MDP). For simplicity, in the following we consider these problems when  $\{X_k\}$  and  $\{Y_k\}$  are *i.i.d.* We obtain the existence of optimal  $\alpha$ -discount and average cost stationary Markov policies.

**Theorem 3:** Let  $g$  be continuous and let the energy buffer be finite, i.e.,  $e_k \leq \bar{e} < \infty$ . Also, assume that  $(X, Y)$  are discrete random variables or have a probability density. Then there exists an optimal  $\alpha$ -discounted Markov stationary policy. If in addition  $E[X] < g(E[Y])$  and  $E[X^2] < \infty$ , then there exists an average cost optimal stationary Markov policy. The optimal cost  $v$  does not depend on the initial state. Also, then the optimal  $\alpha$ -discount policies tend to an optimal average cost policy as  $\alpha \rightarrow 1$ . Furthermore, if  $v_\alpha(q, e)$  is the optimal  $\alpha$ -discount cost for the initial state  $(q, e)$  then  $\lim_{\alpha \rightarrow 1} (1 - \alpha) \inf_{(q, e)} v_\alpha(q, e) = v$ .

*Proof:* We use Prop. 2.1 in [24] to obtain the existence of an optimal  $\alpha$ -discount stationary Markov policy. For this it is sufficient to verify the condition (W) in [24]. The actions possible in state  $(q_k, E_k) = (q, e)$  are  $0 \leq T_k \leq e$ . This forms a compact subset of the action space. Also this mapping is upper and lower semicontinuous. Under action  $t$ , the next state becomes  $((q - g(t))^+ + X_k, e - t + Y_k)$ . When  $g$  is continuous, the mapping  $t \mapsto ((q - g(t))^+ + X_k, e - t + Y_k)$  is a.s. continuous and hence the transition probability is continuous under weak convergence topology. In fact it converges under the stronger topology of setwise convergence. Also, the cost  $(q, e) \mapsto q$  is continuous. Thus condition (W) in [24] is satisfied. Not only we get existence of  $\alpha$ -discount optimal policy, from [25], we also get  $v_n(q, e) \rightarrow v_\alpha(q, e)$  as  $n \rightarrow \infty$  where  $v_n(q, e)$  is  $n$ -step optimal  $\alpha$ -discount cost.

To get the existence of an average cost optimal stationary Markov policy, we use Theorem 3.8 in [24]. This requires satisfying condition (B) in [24] in addition to condition (W). Let  $J_\alpha(\delta, (q, e))$  be the  $\alpha$ -discount cost under policy  $\delta$  with initial state  $(q, e)$ . Also let  $m_\alpha = \inf_{(q, e)} v_\alpha(q, e)$ . Then we

need to show that, for all  $(q, e)$ ,

$$\sup_{\alpha < 1} (v_\alpha(q, e) - m_\alpha) < \infty. \quad (8)$$

For this we use the TO policy described in Section II. We have shown that for this policy there is a unique stationary distribution and if  $E[X^2] < \infty$  then  $E[q] < \infty$  under stationarity.

Next we use the facts that  $v_\alpha(q, e)$  is non-decreasing in  $q$  and non-increasing in  $e$ . We will prove these at the end of this proof. Then  $m_\alpha = v_\alpha(0, \bar{e})$ .

Let  $\tau$  be the first time  $q_k = 0, E_k = \bar{e}$  when we use the TO policy. Under our conditions  $E[\tau] < \infty$  if  $q_0 = 0$  for any  $e_0 = e$ . Also, then

$$v_\alpha(q, e) \leq E \left[ \sum_{k=0}^{\tau-1} \alpha^k q_k | q_0 = q, e_0 = e \right] + v_\alpha(0, \bar{e}).$$

Thus,  $v_\alpha(q, e) - v_\alpha(0, \bar{e}) \leq E \left[ \sum_{k=0}^{\tau-1} q_k | q_0 = q, e_0 = e \right]$ . For notational convenience in the following inequalities we omit writing conditioning on  $q_0 = q, e_0 = e$ . The RHS

$$\begin{aligned} &\leq E \left[ \sum_{k=0}^{\tau-1} (q + \sum_{l=0}^k X_l) \right] \leq E \left[ \sum_{k=0}^{\tau-1} (q + \sum_{l=0}^{\tau-1} X_l) \right] \\ &= qE[\tau] + E \left[ \tau \sum_{l=0}^{\tau-1} X_l \right] \\ &\leq qE[\tau] + E[\tau^2]^{\frac{1}{2}} E \left[ \left( \sum_{l=0}^{\tau-1} X_l \right)^2 \right]^{\frac{1}{2}}. \end{aligned}$$

Since  $\{X_k\}$  are *i.i.d.* and  $\tau$  is a stopping time,  $E \left[ \left( \sum_{l=0}^{\tau-1} X_l \right)^2 \right] < \infty$  if  $E[\tau^2] < \infty$  and  $E[X^2] < \infty$  ([26]). In Lemma 2 in the Appendix we will show that  $E[\tau^2] < \infty$  for any initial condition for the TO policy when  $E[X^2] < \infty$ . Thus we obtain  $\sup_{(0 \leq \alpha < 1)} (v_\alpha(q, e) - v_\alpha(0, \bar{e})) < \infty$  for each  $(q, e)$ . This proves (8).

Now we show that  $v_\alpha(q, e)$  is non-decreasing in  $q$  and non-increasing in  $e$ . Let  $v_n$  be  $n$ -step  $\alpha$ -discount optimal cost where  $v_0 = c$ , a constant. Then  $v_n$  satisfies

$$v_{n+1}(q, e) = \min_t \{q + \alpha E[v_n((q - g(t))^+ + X, e - t + Y)]\}. \quad (9)$$

To prove our assertion, we use induction.  $v_0(q, e)$  satisfies the required properties. Let  $v_n(q, e)$  also do so. Then from (9) it is easy to show that  $v_{n+1}(q, e)$  also satisfies these monotonicity properties. We have shown above that  $v_\alpha(q, e) = \lim_{n \rightarrow \infty} v_n(q, e)$ . Thus  $v_\alpha(q, e)$  inherits these properties. ■

In Section III we identified a throughput optimal policy when  $g$  is nondecreasing, concave. Theorem 3 guarantees the existence of an optimal mean delay policy. It is of interest to identify one such policy also. In general one can compute a delay optimal policy numerically via Value Iteration or Policy Iteration. But this can be computationally intensive. Also it does not provide any insight and requires traffic and energy profile statistics.

In Section III, we also provided a greedy policy (5) which is very intuitive, and is throughput optimal for linear  $g$ . Next we show that it provides minimum mean delay for linear  $g$ . This happens because for linear  $g$  there is no penalty to pay in

using more energy and hence it is optimal to clear the queue as early as possible from short term as well as long term point of view. Therefore, as the following theorem proves, Greedy policy is  $\alpha$ -discount as well as average cost optimal.

**Theorem 4:** The Greedy policy (5) is  $\alpha$ -discount optimal for  $0 < \alpha < 1$  when  $g(t) = \gamma t$  for some  $\gamma > 0$ . It is also average cost optimal.

*Proof:* We first prove the optimality for  $0 < \alpha < 1$  where the cost function is  $J_\alpha(\delta, q, e) = E \left[ \sum_{k=0}^{\infty} \alpha^k q_k \right]$  for a policy  $\delta$ . Let there be an optimal policy that violates (5) at some time  $k$ , i.e.,  $t_k \neq \min \left( \frac{q_k}{\gamma}, E_k \right)$ . Clearly  $t_k \leq E_k$ . Also taking  $t_k > q_k/\gamma$  wastes energy and hence cannot be optimal. The only possibility for an optimal policy to violate (5) is when  $t_k < q_k/\gamma$  and  $q_k/\gamma \leq E_k$ . This is done with the hope that using the extra energy  $\tilde{t}_k - t_k$  (where  $\tilde{t}_k \triangleq q_k/\gamma$ ) later can possibly reduce the cost. However this *increases* the total cost by at least

$$\gamma \alpha^k (\tilde{t}_k - t_k) - \gamma \alpha^{k+1} (\tilde{t}_k - t_k) = \gamma \alpha^k (\tilde{t}_k - t_k) (1 - \alpha) > 0$$

on that sample path. Thus such a policy can be improved by taking  $t_k = \tilde{t}_k$ . This holds for any  $\alpha$  with  $0 < \alpha < 1$ . Also, from Theorem 3, under the conditions given there, an  $\alpha$ -discount optimal policy converges to an average cost optimal policy as  $\alpha \nearrow 1$ . This shows that (5) is also average cost optimal. ■

## V. GENERALIZATIONS

In this section, we make our model more realistic by relaxing several assumptions made in Section II. In particular, we take into account energy inefficiency in storing energy in the energy buffer, energy leakage from the energy buffer, and battery relaxation effects ([27]). Next, we consider channel fading and the energy consumption in sensing and processing.

We assume that if energy  $Y_k$  is generated in slot  $k$ , then only energy  $\beta_1 Y_k$  is stored in the buffer where  $0 < \beta_1 < 1$  and that in every slot, energy  $\beta_2$  gets leaked from the buffer,  $0 < \beta_2 < \infty$ . These seem to be realistic assumptions [11]. Then (2) becomes

$$E_{k+1} = ((E_k - T_k) - \beta_2)^+ + \beta_1 Y_k \quad (10)$$

Now, Lemma 1 and Theorem 1 continue to hold with obvious changes and for energy neutral operation, our TO policy becomes  $T_k = \beta_1 E[Y] - \beta_2 - \epsilon$  for a small positive  $\epsilon$  (although it is no longer throughput optimal). A similar modification in (5) provides a greedy policy. Theorems 2, 3 and 4 also continue to hold.

The modification (10) reduces the stability region to  $E[X] < g(\beta_1 E[Y] - \beta_2)$ . If the energy harvested  $Y_k$  in slot  $k$  is immediately used (instead of first storing in the buffer) then (10) becomes

$$E_{k+1} = \left( (E_k + \beta_1(Y_k - T_k))^+ - (T_k - Y_k)^+ - \beta_2 \right)^+.$$

Now if we take  $T_k = Y_k$  for all  $k$  then of course the stability condition is  $E[X_k] < E[g(Y_k)]$  which may be a larger stability region than that provided by (10). Another good policy which is energy neutral is  $T_k \equiv c$  where  $c$  is the largest constant with  $\beta_1 E[(Y_k - c)^+] > E[(c - Y_k)^+] + \beta_2$ . The stability condition for this is  $E[X] < g(c)$ .

The energy storage device can be a rechargeable battery and/or a supercapacitor ([16]). A rechargeable battery has an extra feature of regaining some charge when it is not being used via *recovery effect* ([27]). The recovered charge/energy depends on the charge it already has and the battery idle time in a nonlinear way. It is possible to extend our theory to cover this phenomenon at some extra effort. However, in the present context recovery effect may not be relevant because the charge recovery happens mainly when the discharge current in the battery varies substantially in time. In our TO policy, we always use  $T_k = E[Y] - \epsilon$ . Also for all the policies, there is energy spent for sensing and processing (see end of this section) which is non-negligible, at least in the more recent sensor nodes. Thus, this phenomenon may be observed only when the sensor node is in a sleep mode (a power saving mode) which is not considered in this paper (see however [28]).

We consider two further generalizations. First we extend the results to the case of fading channels and then to the case where the sensing and the processing energy at a sensor node are non-negligible with respect to the transmission energy.

In case of fading channels, we assume flat fading during a slot. This is a reasonable assumption for wireless sensor networks where the coherence bandwidth is generally greater than 50 MHz whereas the transmission bandwidths are much less. In slot  $k$  the channel gain is  $h_k$ . The sequence  $\{h_k\}$  is assumed stationary, ergodic, independent of the traffic sequence  $\{X_k\}$  and the energy generation sequence  $\{Y_k\}$ . If  $T_k$  energy is spent in transmission in slot  $k$ , the  $\{q_k\}$  process evolves as

$$q_{k+1} = (q_k - g(h_k T_k))^+ + X_k.$$

If the channel state information (CSI) is not known to the sensor node, then  $T_k$  will depend only on  $(q_k, E_k)$ . One can then consider the policies used above. For example we could use  $T_k = \min(E_k, E[Y] - \epsilon)$ . Then the data queue is stable if  $E[X] < E[g(h(E[Y] - \epsilon))]$ . We will call this policy unfaded TO. If we use Greedy (5), then the data queue is stable if  $E[X] < E[g(hY)]$ . An approximate practical implementation of this can be done via rateless codes.

If CSI  $h_k$  is available to the node at time  $k$ , then the following are the throughput optimal policies. If  $g$  is linear, then  $g(x) = \alpha x$  for some  $\alpha > 0$ . Then, if  $0 \leq h \leq \bar{h} < \infty$  and  $P(h = \bar{h}) > 0$ , the optimal policy is:  $T(\bar{h}) = (E[Y] - \epsilon)/P(h = \bar{h})$  and  $T(h) = 0$  otherwise. Thus if  $h$  can take an arbitrarily large value with positive probability, then  $E[hT(h)] = \infty$  at the optimal solution.

If  $g(x) = \frac{1}{2} \log(1 + \beta x)$ , then the water filling (WF) policy

$$T_k(h) = \left( \frac{1}{h_0} - \frac{1}{h} \right)^+ \quad (11)$$

with the average power constraint  $E[T_k] = E[Y] - \epsilon$ , is throughput optimal because it maximizes  $\frac{1}{2} E_h[\log(1 + \beta h T(h))]$  with the given constraints. For a general concave  $g$ , we can obtain the optimal power control policy numerically with the average power constraint  $E[T_k] = E[Y] - \epsilon$ .

Both of the above policies can be improved as before, by not wasting energy when there is not enough data. As in (6)

in Section III, we can further improve WF by taking

$$T_k = \min \left( g^{-1}(q_k), E_k, \left( \frac{1}{h_0} - \frac{1}{h} + 0.001(E_k - cq_k)^+ \right)^+ \right). \quad (12)$$

We will call it MWF. These policies do not minimize mean delay. For that, we can use the MDP framework used in Section IV and numerically compute the optimal policies.

Till now we have assumed that all the energy that a node consumes is for transmission. However, sensing, processing and receiving (from other nodes) also require significant energy, especially in more recent higher end sensor nodes ([13]). Since we have been considering a single node so far, we now include the energy consumed by sensing and processing only. For simplicity, we assume that the node is always in one energy mode (e.g., lower energy modes [6] available for sensor nodes are not considered). If a sensor node with an energy harvesting system can be operated in energy neutral operation in normal mode itself (i.e., it satisfies the conditions in Lemma 1), then there is no need to have lower energy modes. Otherwise one has to resort to energy saving modes.

We assume that  $Z_k$  is the energy consumed by the node for sensing, processing and other miscellaneous operations in slot  $k$ . Unlike  $T_k$  (which can vary according to  $q_k$ ),  $\{Z_k\}$  can be considered a stationary ergodic sequence. The rest of the system is as in Section II. Now we briefly describe a energy management policy which is an extension of the TO policy in Section III. This can provide an energy neutral operation in the present case. Improved/optimal policies can be obtained for this system also but will not be discussed due to lack of space.

Let  $c$  be the minimum positive constant such that  $E[X] < g(c)$ . Then if  $c + E[Z] < E[Y] - \delta$ , (where  $\delta$  is a small positive constant) the system can be operated in energy neutral operation: If we take  $T_k \equiv c$  (which can be done with high probability for all  $k$  large enough), the process  $\{q_k\}$  will have a unique stationary, ergodic distribution and there will always be energy  $Z_k$  for sensing and processing for all  $k$  large enough. The result holds if  $\{(X_k, Y_k, Z_k)\}$  is an ergodic stationary sequence. The arguments to show this are similar to those in Section III and are omitted.

When the channel has fading, we need  $E[X] < E[g(ch)]$  in the above paragraph.

## VI. SIMULATIONS

In this section, we compare the different policies we have studied via simulations. Then, we evaluate the performance of the Greedy policy and Throughput Optimal policy for data buffers of finite size. In the last part of the section, we provide results of a simulation done for a real-world setting.

Initially, we take the  $g$  function as linear ( $g(x) = 10x$ ) or as  $g(x) = \log(1 + x)$ . The sequences  $\{X_k\}$  and  $\{Y_k\}$  are *i.i.d.* (We have also done limited simulations when  $\{X_k\}$  and  $\{Y_k\}$  are Autoregressive and found that conclusions drawn in this section continue to hold). We consider the cases when  $X$  and  $Y$  can have exponential, Erlang or Hyperexponential distributions. The policies considered are: Greedy, TO,  $T_k \equiv Y_k$ , MTO (with  $c = 0.1$ ) and the mean delay optimal. We also consider channels with fading. For the linear  $g$ , we already

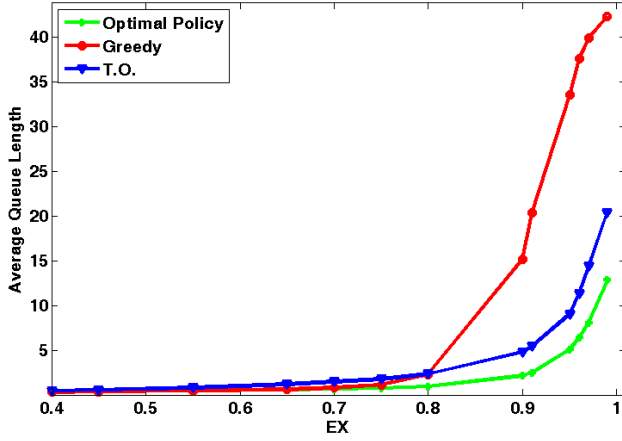

Fig. 2. Mean delay optimal, greedy, TO policies with no fading; nonlinear  $g$ ; finite, quantized data and energy buffers;  $X, Y$ : Poisson truncated at 5;  $E[Y] = 1$ ,  $E[g(Y)] = 0.92$ ,  $g(E[Y]) = 1$ .

Fig. 3. Comparison of policies with no fading;  $g(x) = 10x$ ;  $X, Y$ : exponential;  $E[Y] = 1$ ,  $E[g(Y)] = 10$ ,  $g(E[Y]) = 10$ .

know that the Greedy policy is throughput optimal as well as mean delay optimal.

The mean queue lengths for the different cases are plotted in Figs. 2-8 for infinite buffer case. Thus, via Little's law, we can obtain the mean delays also.

In Fig. 2, we compare Greedy, TO and mean-delay optimal (OP) policies for nonlinear  $g$ . The OP was computed via Policy Iteration. For numerical computations, all quantities need to be finite and quantized. The number of computations required would depend on the size of the state space and thus, on the quantization. We took data and energy buffer sizes to be 50 and used quantized versions of  $q_k$  and  $E_k$ . The distribution of  $X$  and  $Y$  is Poisson truncated at 5. These changes were made only for this example. Now  $g(E[Y]) = 1$  and  $E[g(Y)] = 0.92$ . We see that the mean queue length of the three policies are negligible till  $E[X] = 0.8$ . After that, the mean queue length of the Greedy policy rapidly increases while performances of the other two policies are comparable till 1 (although from  $E[X] = 0.6$  till close to 1, mean queue length of TO is approximately double of OP). At low loads, Greedy has less mean queue length than TO.

Fig. 3 considers the case when  $X$  and  $Y$  are exponential and

Fig. 4. Comparison of policies with no fading;  $g(x) = \log(1+x)$ ;  $X, Y$ : exponential;  $E[Y] = 10$ ,  $E[g(Y)] = 2.01$ ,  $g(E[Y]) = 2.4$ .

Fig. 5. Comparison of policies with no fading;  $g(x) = \log(1+x)$ ;  $X, Y$ : Erlang(5);  $E[Y] = 10$ ,  $E[g(Y)] = 2.32$ ,  $g(E[Y]) = 2.4$ .

$g$  is linear. Now  $E[Y] = 1$  and  $g(E[Y]) = E[g(Y)] = 10$ . Now all the policies considered are throughput optimal but their delay performances *differ* with the greedy policy having the least delay. We observe that the policy  $T_k \equiv Y_k$  (henceforth called unbuffered) has the worst performance. Next is the TO.

Figs. 4 and 5 provide the above results for  $g$  nonlinear. When  $X$  and  $Y$  are exponential, the results are provided in Fig. 4 and when they are Erlang (obtained by summing 5 exponentials), they are in Fig. 5. Note that exponential distribution has more variability than Erlang. Now, as before  $T_k \equiv Y_k$  is the worst. The Greedy policy performs better than the other policies for low values of  $E[X]$ . But, Greedy becomes unstable at  $E[g(Y)]$  ( $= 2.01$  for Fig. 4 and  $= 2.32$  for Fig. 5) while the throughput optimal policies become unstable at  $g(E[Y])$  ( $= 2.40$  for Fig. 4 and Fig. 5). Now for higher values of  $E[X]$ , the modified TO performs the best and is close to Greedy at low  $E[X]$ .

Figs. 6-8 provide results for fading channels. Fig. 6 is for the linear  $g$  and Figs. 7, 8 are for the nonlinear  $g$ . The policies compared are unbuffered, Greedy, Unfaded TO and Fading TO (WF) (11). In Figs. 7 and 8, we have also considered Modified

Fig. 6. Comparison of policies with fading;  $g(x) = 10x$ ;  $X, Y$ : hyperexponential(5);  $E[Y] = 1, E[g(hY)] = 10, g(hE[Y]) = 10$ .

Fig. 8. Comparison of policies with fading;  $g(x) = \log(1+x)$ ;  $X, Y$ : hyperexponential(5);  $E[Y] = 1, E[g(hY)] = 0.51, E[g(hE[Y])] = 0.64$ ; WF, Mod. WF stable for  $E[X] < 0.70$ .

Fig. 7. Comparison of policies with fading;  $g(x) = \log(1+x)$ ;  $X, Y$ : Erlang(5);  $E[Y] = 1, E[g(hY)] = 0.62, E[g(hE[Y])] = 0.64$ ; WF, Mod. WF stable for  $E[X] < 0.70$ .

Fig. 9. Throughput of greedy policy and TO policy with a finite data buffer (F.B.) of size 50 bits. Plotted alongside are the throughputs for the infinite buffer case.

Unfaded TO (6) and Modified Fading TO (MWF) (12).

In Fig. 6,  $X$  and  $Y$  have Hyperexponential distributions. The distribution of r.v.  $X$  is a mixture of 5 exponential distributions with means  $E[X]/4.9, 2E[X]/4.9, 3E[X]/4.9, 6E[X]/4.9$  and  $10E[X]/4.9$  and probabilities 0.1, 0.2, 0.2, 0.3 and 0.2 respectively. The distribution of  $Y$  is obtained in the same way. For this case only, we consider a simple model for the fading process:  $\{h_k\}$  is *i.i.d.* taking values 0.1, 0.5, 1.0 and 2.2 with probabilities 0.1, 0.3, 0.4 and 0.2 respectively. Now  $E[Y] = 1, E[g(hY)] = 10$  and  $E[g(hE[Y])] = 10$ . We see that the stability region of fading TO is  $E[X] < E[g(hY)]$  ( $= 22.0$ ) while that of the other three algorithms is  $E[X] < 10$ . However, mean queue length of fading TO is also larger from the beginning till almost 10. This is because in fading TO, we transmit only when  $h = \bar{h} = 2.2$  which has a small probability ( $= 0.2$ ) of occurrence. This example shows that for a linear  $g$ , CSI can significantly improve the stability region.

Figs. 7 and 8 consider nonlinear  $g$ . We now consider a more realistic channel with discrete Rayleigh fading where we obtain the fade states by sampling the Rayleigh distribution

at ten values and assigning them appropriate probabilities. In Fig. 7  $X, Y$  are Erlang distributed and in Fig. 8  $X, Y$  are Hyperexponential as in Figs. 5 and 6. In Fig. 7,  $E[Y] = 1, E[g(hY)] = 0.62, E[g(hE[Y])] = 0.64$  while in Fig. 8,  $E[Y] = 1, E[g(hY)] = 0.51$  and  $E[g(hE[Y])] = 0.64$ . Now we see that the stability region of unbuffered and Greedy is the smallest, then of TO and MTO while WF and MWF provide the largest region and are stable for  $E[X] < 0.70$ . MTO and MWF provide improvements in mean queue lengths over TO and WF. The difference in stability regions is smaller for Erlang distribution. This is expected because the Hyperexponential distribution has much more variability than Erlang.

Next, we evaluate the performance of the Greedy policy and TO policy when the data buffer is of finite size. In Figs. 9 and 10,  $g(x) = \log(1+x)$ ,  $E[Y] = 10$  and  $X, Y$  have the same distribution as used in Fig. 6. We see from Fig. 9 that the reduction in throughput for the two policies is minimal even with a small data buffer of size 50 bits. Further, from Fig. 10, we observe that we get a better delay performance at the cost of a small reduction in the throughput by having a finite data buffer.

Fig. 10. Average queue lengths of the greedy policy and TO policy with a finite data buffer (F.B.) of size 50 bits. Plotted alongside are the average queue lengths for the infinite buffer case.

Fig. 11. Queue length for the greedy policy.

Finally, we discuss the results of simulation done for a real world setting in which we consider a Mica2 ([29]) sensor node which is transmitting to another Mica2 node. The node is being powered by two AA-sized NiMH rechargeable batteries which are initially charged to half their capacity. The battery gets recharged by two solar panels (4 – 3.0 – 100 model) each of which has a rating of 3 V and 100 mA. We take the rate of energy harvesting to be proportional to the total solar radiation or the global horizontal radiation. We take it to be 0.3 W for one solar panel when the global horizontal radiation is high (like at noon time). We use the global horizontal radiation data available in [30]. We take  $\beta_1 = 0.7$  and  $\beta_2 = 0$  in (10). These are reasonable assumptions ([11]). Thus, we get  $E[Y] = 5.4 \text{ mJ}$ . Mica2 uses the low power transceiver CC1000 ([31]). We consider CC1000 being used in UART mode in the 868 MHz band and use the corresponding sensitivity data given in the datasheet to obtain the  $g$  function. We found that it could be well approximated by a linear function:  $g(x) = 5.84 \times 10^5 x \text{ bits}$  where  $x$  is the variable<sup>2</sup> part of the energy consumed by the transmitter measured in Joules. Thus, the Greedy policy is delay optimal as well as throughput optimal for this setting. We take a slot of length 50 ms. The sensor generates packets of size 5 bytes. The data buffer for Mica2 is 512 kbytes and the energy buffer is of size 15.5 kJ. The sensing equipment, processor, memory

<sup>2</sup>Even for low transmit powers, a transceiver consumes a significant amount of power. Thus, the total energy consumed by the transceiver consists of a constant and a variable part. The constant part is included in  $Z_k$ .

Fig. 12. Energy buffer for the greedy policy.

operations and transceiver consume energy at the rate of 2.1 mW, 24 mW, 15 mW and 29.8 mW respectively. Thus,  $E[Z] = 3.5 \text{ mJ}$  and  $g(E[Y] - E[Z]) = 1084 \text{ bytes}$  and we consider an *i.i.d.* arrival process with Poisson distribution and mean  $E[X] = 600 \text{ bytes}$ . Figs. 11 and 12 depict the queue length and energy buffer level for simulations done employing the Greedy policy. One sees that there is sufficient energy at all times so that for the Greedy policy,  $T_k = f(q_k) = f(X_k)$  (and for TO policy  $T_k = E[Y_k] - E[Z_k] - \epsilon$ ). Actually, in CC1000, only certain levels of transmit power are allowed (-20 dBm to 5 dBm with steps of 1 dBm) and we took the largest level less than  $f(X_k)$ . We observe that the policy ensures that the queue is stable and has a stationary distribution. Also, we find that the energy buffer is building up. We also did simulations for the TO policy and observed that the data queue was stable and the energy was building up, i.e., we observe an energy neutral operation. The energy buffer (Fig. 12) shows periodicity over a day and we see that the energy buffer is large enough to make the mote work over night uninterrupted. Theoretically, since  $\{Y_k\}$  can be approximated by a periodic, stationary, ergodic process (with period = 1 day), and  $T_k$  is asymptotically stationary (for Greedy and TO policy, as explained above),  $\{E_k\}$  becomes periodic, stationary, ergodic with 1 day period as we observe.

## VII. CONCLUSIONS AND FUTURE DIRECTIONS

We have considered a sensor node with an energy harvesting source which is deployed for random field estimation. Throughput optimal and mean delay optimal energy management policies are identified which can make the system work in energy neutral operation. The mean delays of these policies are compared with other suboptimal policies via simulations. It is found that having energy storage allows larger stability region as well as lower mean delays. Also, often (when energy to transmission rate map  $g$  is linear) a greedy policy studied here is throughput as well as mean delay optimal. This does not require energy harvesting and traffic generation statistics and is easy to implement.

We have extended our results to fading channels and to the scenario when energy at the sensor node is also consumed in sensing and data processing. It is shown that if  $g$  is linear then knowing the state of a fading channel can significantly increase the stability region. We have also included the effects of leakage and inefficiency in storage at the battery. It can

reduce the stability region. However, some of the lost region can be recovered if we immediately use the energy harvested before storing in the buffer. Finally, we have demonstrated our algorithms on a real life data.

We have recently extended this work in various directions. Sleep-wake cycles with energy management have been introduced in [28]. Efficient MAC protocols [32] and joint power control, routing and scheduling protocols [33] have also been developed for sensor networks with energy harvesting nodes.

## VIII. ACKNOWLEDGEMENT

This work was partially supported by a research grant from Boeing Corporation. The comments of the reviewers have significantly improved the presentation.

## IX. APPENDIX

To avoid trivialities, we assume  $P[X_k > 0] > 0$ . For the following lemma, we also assume that  $P[X_k = 0] > 0$ .

**Lemma 2:** When  $\{X_k\}, \{Y_k\}$  are *i.i.d.*,  $E[X] < g(E[Y] - \epsilon)$ ,  $e \leq \bar{e}$ , and  $E[X^\alpha] < \infty$  for some  $\alpha \geq 1$  then  $\tau \triangleq \inf\{k \geq 1 : (q_k, E_k) = (0, \bar{e})\}$  satisfies  $E[\tau^\alpha] < \infty$  for any  $(q_0, E_0) = (q, e)$ .

*Proof:* Let  $A = \{(q, e) : q + e \leq \beta\}$  where  $\beta$  is an appropriately defined positive, finite constant. We first show that starting from any initial  $(q_0, E_0) = (q, e)$  the first time  $\bar{\tau}$  to reach  $A$  satisfies  $E[\bar{\tau}^\alpha] < \infty$ . Next we show that with a positive probability in a finite (bounded) number of steps  $(q_k, E_k)$  can reach from  $A$  to  $(0, \bar{e})$ . Then by a standard coin tossing argument, we obtain  $E[\tau^\alpha] < \infty$ .

To show  $E[\bar{\tau}^\alpha] < \infty$ , we use a result in [[34], pp.116]. Then it is sufficient to show that for  $h(q, e) = q$ ,

$$\sup_{(q,e) \notin A} E[h(q_1, E_1) - h(q, e) | q_0 = q, E_0 = e] < -\delta \quad (13)$$

for some  $\delta > 0$  and for all  $(q, e)$ ,

$$E[|h(q_1, E_1) - h(q, e)|^\alpha | (q_0, E_0) = (q, e)] < \infty. \quad (14)$$

Instead of using (13), (14) on the Markov chain  $\{(q_k, E_k)\}$  we use it on the Markov chain  $\{(q_{Mk}, E_{Mk}), k \geq 0\}$  where  $M > 0$  is an appropriately large positive integer. Thus for (14) we have to show that  $E[|q_M - q|^\alpha | q_0 = q] < \infty$  which holds if  $E[X^\alpha] < \infty$ .

Next we show (13). Taking  $\beta$  large enough, since  $T_k \leq \bar{e}$ , we get for  $(q, e) \notin A$ ,

$$\begin{aligned} & E[h(q_M, E_M) - h(q_0, E_0) | (q_0, E_0) = (q, e)] \\ &= E\left[q + \sum_{n=0}^M (X_n - g(T_n)) - q | (q_0, E_0) = (q, e)\right]. \end{aligned}$$

Thus, (13) is satisfied if

$$E[X_1] < \frac{1}{M} \sum_{k=1}^M E[g(T_n) | (q_0, E_0) = (q, e)] - \delta. \quad (15)$$

But for TO,

$$\begin{aligned} & \frac{1}{M} \sum_{k=1}^M E[g(T_n) | (q_0, E_0) = (q, e)] \\ &= \frac{1}{M} \sum_{k=1}^M E[g(T_n) | E_0 = e] \rightarrow g(E[Y] - \epsilon) \end{aligned}$$

and thus there is an  $M$  (choosing one corresponding to  $e = 0$  will be sufficient for other  $e$ ) such that if  $E[X] < g(E[Y] - \epsilon)$ , then (15) will be satisfied for some  $\delta > 0$ .

Now we show that from any point  $(q, e) \in A$ , the process can reach the state  $(0, \bar{e})$  with a positive probability in a finite number of steps. Choose positive  $\epsilon_1, \epsilon_2, \epsilon_3, \epsilon_4$  such that  $P[X_k = 0] = \epsilon_1 > 0$  and  $P[Y_k > \epsilon_3] > \epsilon_4$ ,  $g(\epsilon_3) = \epsilon_2$ , where such positive constants exist under our assumptions.

Then with probability  $\geq (\epsilon_1 \epsilon_4)^{\left(\left\lceil \frac{\beta}{\epsilon_2} \right\rceil + \left\lceil \frac{\bar{e}}{\epsilon_3} \right\rceil\right)}$ ,  $(q_k, E_k)$  reaches  $(0, \bar{e})$  in  $\left\lceil \frac{\beta}{\epsilon_2} \right\rceil + \left\lceil \frac{\bar{e}}{\epsilon_3} \right\rceil$  steps where  $\lceil x \rceil$  is the smallest integer  $\geq x$ . ■

ADVANCED COMPUTER ENGINEERING, Serials Publications. Prof Sharma's research interests are in Wireless Communication, Information Theory and Communication Networks.

Systems Research Department at AT&T Bell Laboratories, Murray Hill, NJ, from 1986 to 1989. His research interests are in the area of modelling, analysis, control, and optimisation of communication networks.

Wireless Communication Networks and Stochastic Processes.

**Vinod Sharma** completed his BTech in 1978 from IIT Delhi and PhD in 1984 from CMU in Pittsburgh in Electrical Engg. He worked in Northeastern Univ in Boston and UCLA before joining Indian Institute of Science in 1988 where currently he is a Professor and Chairman of Electrical Communication Engg Dept. He is on the editorial boards of the INTERNATIONAL JOURNAL OF INFORMATION AND CODING THEORY, Inderscience, the JOURNAL OF ELECTRICAL AND COMPUTER ENGINEERING, Hindawi, and the INTERNATIONAL JOURNAL OF

**Utpal Mukherji** is an Associate Professor in the Department of Electrical Communication Engineering at the Indian Institute of Science, Bangalore. He obtained the Bachelor of Technology degree in Electrical Engineering in 1980 from the Indian Institute of Technology, Bombay, and the Master of Science, Electrical Engineer, and Doctor of Science degrees in Electrical Engineering and Computer Science from the Massachusetts Institute of Technology in 1982, 1984, and 1986, respectively. He was a Member of Technical Staff in the Distributed

**Vinay Joseph** received his B.Tech. in Electronics and Communication Engineering in 2007 from National Institute of Technology, Calicut, India, and his M.E. in Telecommunication Engineering from Indian Institute of Science, Bangalore, India in 2009. He is currently a Ph.D. student in the Department of Electrical and Computer Engineering at The University of Texas at Austin. He is a recipient of the Microelectronics and Computer Development Fellowship from The University of Texas at Austin. His research interests are broadly in the areas of

**Shrey Gupta** received his B.Tech. degree in Computer Science and Engineering from the Indian Institute of Technology, Guwahati, India, in 2009. He is currently working toward a M.S. degree at the Department of Computer Science, Stanford University. His research interests include protocol design for networks, algorithms and machine learning.

He was a recipient of the summer research fellowship awarded jointly by the Indian Academy of Sciences, Indian National Science Academy and the National Academy of Sciences, India in the year

2007. He has also been associated with the Indian Institute of Science, Bhabha Atomic Research Centre and Qualcomm Research & Development as a research intern.
